Test a (causal) hypothesis with observational data (THE III - All)

Research Design and Methods in Quantitative Research - Fall 2026

Dr. K. Jonathan Klüser

2026-10-29

Instructions

Please read and follow the guidelines below carefully. Then, complete the exercises and report the results in a Quarto document. Compile the Quarto document in PDF and submit both the compiled PDF and `.qmd` files within the deadline.

Further instructions about the submission are below.

Preparation: Download the CSES Integrated Module Dataset (IMD)

(It is assumed that you installed R and RStudio, and learned to prepare a Quarto document for the previous Take-Home Exercises. In case of doubt, you can consult the preparation guidelines for Take-Home Exercise I.)

The Comparative Study of Electoral Systems (CSES) is a standardized post-electoral cross-national survey that covers most democratic countries worldwide. It has been running since 1996 until now. The CSES Integrated Module Dataset (IMD) include selected variables from CSES Modules 1 through 5 into a single, harmonized longitudinal dataset. Variables included in the IMD must appear in at least three CSES Modules, up to and including Module 5. The dataset encompasses all polities that participated in these modules, featuring over 395,000 individual-level observations from 230 elections across 59 polities. Notable features of the CSES IMD include harmonized numerical codes for parties and coalitions within polities across modules, a pre-coded variable for incumbent vote choice, political information indexes, comprehensive macro-level data spanning over 25 years, and detailed within-dataset labels for all parties and coalitions.

For this exercise, you will need to register in the CSES webpage and download the CSES IMD. For easy integration with R, I recommend downloading the following file:

- cses_imd_r.zip

You will also need the codebook.

Exercises

Exercise 1: Draw a DAG of the causal hypothesis

You will use the CSES IMD data to test one of the most prominent theories in political science: the **economic voting theory**. This theory states that citizens decide their vote based on the state of the economy, so that they are more likely to support the incumbent (i.e., the outgoing governing party or candidate) if the economy works well and less likely is the economic situation is bad (for a review, see Lewis-Beck and Stegmaier, 2018). Focusing on citizens' perceptions rather than objective economic indicators, the following (causal) hypothesis follows:

> **Hypothesis**: Negative (positive) economic evaluations reduce (increase) the probability of voting for the incumbent.

The CSES data contains one variable that we can use as our independent (*"treatment"*) variable, as it is operationalized as follows:

- `IMD3013_1`: Would you say that over the past twelve months, the state of the economy in [COUNTRY] has gotten better, stayed about the same, or gotten worse?

It also contains a variable that we can use to measure voting for the incumbent (i.e., our dependent variable):

- `IMD3002_OUTGOV`: Whether or not the respondent cast a ballot for the outgoing incumbent.

Since we want to approximate a causal test, we will need to control for some variables in order to rule out endogeneity concerns. However, we do not want to do this blindly but based on theoretical reasoning. As you will see in the codebook, there are many variables that we can use (and more that we can construct) to try to isolate the causal relationship between economic evaluations and voting for the incumbent, but we do not want to use them all. To guide our model specification, **please draw a DAG of the theoretical relationship at hand**. This will guide our next choices, so it is important that it is done carefully.

You can draw a DAG in R using the packages `dagitty` and `ggdag` (see installation and loading below). Alternatively, you can draw it with any other program or by hand and upload it to the .qmd document as an image. Please comment your decisions.

PS: Remember to simplify and do not include every variable you think it could be involved in the relationship, but only the most important. Also, group variables under broader concepts to

avoid overfitting the DAG (e.g., 'socio-economic conditions' instead of 'employment status' and 'income').

```
# Install packages
#install.packages(c("dagitty", "ggdag"))

# Load necessary libraries
library(tidyverse)
library(dagitty)
library(ggdag)
```

Exercise 2: Prepare your data

Based on your DAG, declare which control variables you will use for the analysis. Use at least two, but you can add as many as you want (or think would be helpful). Remember, however, that **more is not necessarily better**.

Please inspect and transform these variables when necessary (e.g., recode missing values, invert scales, etc.). Report your code and comment on your decisions.

Exercise 3: Test your hypothesis with an ordinary-least squares (OLS) multiple regression model

Run an OLS regression model to test your hypothesis. For that, use the function `lm()`, or a more advanced one if preferred.

Please comment on your choices and your results. Would you say that the evidence support the *economic voting* hypothesis? Why?

Exercise 4: Plot the model predicted values with confidence intervals *(OPTIONAL)*

This is an optional exercise. It does not count for the grade, so you can still get a 6 without doing it. However, it can compensate for weaker performance in one of the other exercises.

Using your model from *Exercise 3*, generate predicted probabilities (or predicted values) for your main independent variable while holding control variables constant. Plot these predictions with 95% confidence intervals. Then write a brief interpretation of what the plot shows and whether it aligns with your hypothesis.

Hint: you can calculate the predicted probabilities and confidence intervals first and then plot them with `ggplot`*, or you can use the* `marginaleffects/ggeffects` *packages to compute and plot the predicted values directly.*

Exercise 5: Run a baseline (bivariate) OLS model

Re-estimate your regression model without any control variables and compare the results to the model from *Exercise 3*.

Briefly describe how the coefficients differ, explain why these changes may occur, and discuss what this reveals about the role of control variables in your analysis.

Exercise 6: Run an additional OLS model specification *(OPTIONAL)*

This is an optional exercise. It does not count for the grade, so you can still get a 6 without doing it. However, it can compensate for weaker performance in one of the other exercises.

Run an additional OLS regression model specification to explore how sensitive your results are to alternative modeling choices. For this, modify the set of control variables used in your *Exercise 3* model to address potential endogeneity concerns that the initial specification may not fully capture. These changes should reflect alternative assumptions about the underlying causal structure (e.g., adding controls that your original DAG treated as irrelevant but that could still plausibly act as confounders).

First, explain the reasoning behind your changes and comment on the new results.

Second, compare the results from all three models. What is your final assessment of whether there is evidence for or against the economic voting hypothesis?

Submission guidelines

Please submit both the PDF file and the `.qmd` file. Both files should report all the code used for analysis and annotations explaining each step.

The name of the files must follow the structure *take-home_exercise_iii_YOURSURNAME(S).pdf* and *take-home_exercise_iii_YOURSURNAME(S).qmd*, respectively. They should be uploaded to the folder *Students responses/Take-home exercises/Take-home exercise III* in OLAT.

Deadline: **12.11.26**
